Update on the effects of physical activity on insulin sensitivity in humans

Stephen R Bird,1 John A Hawley2,3

ABSTRACT

Purpose and methods: This review presents established knowledge on the effects of physical activity (PA) on whole-body insulin sensitivity (SI) and summarises the findings of recent (2013–2016) studies.

Discussion and conclusions: Recent studies provide further evidence to support the notion that regular PA reduces the risk of insulin resistance, metabolic syndrome and type 2 diabetes, and SI improves when individuals comply with exercise and/or PA guidelines. Many studies indicate a dose response, with higher energy expenditures and higher exercise intensities, including high intensity interval training (HIIT), producing greater benefits on whole-body SI, although these findings are not unanimous. Aerobic exercise interventions can improve SI without an associated increase in cardiorespiratory fitness as measured by maximal or peak oxygen consumption. Both aerobic and resistance exercise can induce improvements in glycaemic regulation, with some suggestions that exercise regimens including both may be more efficacious than either exercise mode alone. Some studies report exercise-induced benefits to SI that are independent of habitual diet and weight loss, while others indicate an association with fat reduction, hence the debate over the relative importance of PA and weight loss continues. During exercise, muscle contraction stimulated improvements in SI are associated with increases in AMPK activity, which deactivates TCB1D1, promoting GLUT4 translocation to the cell membrane and thereby increasing glucose uptake. Postexercise, increases in Akt deactivate TCB1D4 and thereby increase GLUT4 translocation to the cell membrane. The reduction in intramuscular saturated fatty acids and concomitant reductions in ceramides, but not diacylglycerols, provide a potential link between intramuscular lipid content and SI. Increased skeletal muscle capillarisation provides another independent adaptation through which SI is improved, as does enhanced β cell activity. Recent studies are combining exercise interventions with dietary and feeding manipulations to investigate the potential for augmenting the exercise-induced improvements in SI and glycaemic control.

INTRODUCTION

Individuals with poor insulin sensitivity (SI) are characterised by impaired insulin action on whole-body glucose uptake. This results in elevated blood (glucose), impaired glycaemic control, a risk of pancreatic β cell failure and the development of type 2 diabetes (T2D). In developed countries the prevalence of this prediabetic state is currently reported to be 15–20%.1 Furthermore, it is estimated that 366 million people, ~8% of the population are affected by diabetes worldwide,3 hence strategies for the treatment of the prediabetic state, its prevention and preventing progression from prediabetes to T2D are an imperative. Key among these is the inclusion of physical activity (PA) into a healthy lifestyle, and current research in this field continues to seek to understand the behavioural and molecular aspects of exercise in preventing diabetes and poor SI, with the intent to identify efficacious exercise interventions.

The comparison of results between research studies into the effects of a physically active lifestyle and/or exercise on insulin sensitivity and glycaemic control are problematic due to differences in the methods of assessment of outcome variables. While the precise protocols vary, the general methods for assessing insulin sensitivity/glycaemic control include: (1) measuring fasting insulin concentrations, with elevated fasted (insulin) >25 mIU/L indicating poor insulin sensitivity, as the pancreas endeavours to compensate for the lack of peripheral insulin sensitivity by secreting greater amounts of insulin, thereby resulting in hyperinsulinaemia; (2) oral glucose tolerance testing (OGTT), which involves the ingestion of a standard glucose bolus (75 g), followed by blood glucose monitoring for the subsequent 2 hours. Blood glucose concentrations of >7.8 mmol/L and <11.0 mmol/L at 2 hours are indicative of impaired glycaemic control, and >11.0 mmol/L indicates diabetes; (3) hyperinsulinaemic-euglycaemic clamp, in which the participant is infused with insulin at a known rate, creating a hyperinsulinaemic state (~100 µU/ml), while simultaneously blood glucose levels are...
monitored and adjusted by a variable-rate infusion to maintain glycaemia (5.0–5.5 mmol/L). A high rate of glucose infusion indicates insulin sensitivity as the glucose is being rapidly taken up by the cells of the body, while a low rate of glucose infusion indicates a loss of insulin sensitivity, as the glucose is remaining in the blood rather than being taken up by the cells of the body; 3 (4) hyperglycaemic clamp, in which plasma glucose levels are initially increased to ~125 mg/dl above basal values and then maintained at this hyperglycaemic level, through the infusion of glucose. High infusion rates indicate good insulin sensitivity, while low infusion rates indicate insulin resistance (IR). 7; (5) homoeostatic model assessment of insulin resistance (HOMA-IR), which uses fasting (glucose) and insulin, and is calculated as (glucose mmol/L x insulin)/22.5, with a relatively low score indicating well regulated fasting glucose that is being maintained through relatively low concentrations of insulin, hence good insulin sensitivity, whereas an elevated HOMA-IR value, such as >2.5 indicates IR. In the updated homoeostatic model, HOMA2-IR, values >1.5 suggest IR; (6) HOMA-β is a measure of β cell function derived from fasting values using the equation (20 x insulin)/(glucose mmol/L−3.5) %, with this measure indicating the extent to which a deficient β cell function, as opposed to IR, contributes to hyperglycaemia in the fasting state; (7) Quantitative Insulin Sensitivity Check Index (QUICKI), which is an index of insulin sensitivity, calculated as QUICKI=1/(log (fasting plasma insulin μU/ml) + log (fasting blood glucose mg/dL)). 4 Regardless of the methods used to assess insulin sensitivity/glycaemic control, a lifestyle incorporating regular PA has been identified as a key factor for maintaining and improving many aspects of health, including insulin sensitivity. 5 6 In this context, the term PA covers all forms of muscular movement, including that associated with strenuous physical work, active transport (walking and cycling), household tasks (cleaning and gardening), incidental PA which occurs when undertaking other tasks, sport and other active leisure pursuits. Whereas the term ‘exercise’ refers specifically to the context of PA that is undertaken with the specific intent of improving health and/or fitness and is therefore a subset of PA. Hence many cross-sectional studies investigate PA levels as well as specific exercise habits, but interventions tend to involve exercise, as they have the specific intent of affecting an aspect of health. Cross-sectional studies identify an association between regular PA and/or aerobic fitness and superior SI. 5 6 Adding further support to this association, studies involving exercise interventions usually report an amelioration or in some cases, complete reversal of IR. 7 8 Assessments of the impact of a physically active lifestyle suggest a dose response with each 500 kcal/week increase in PA, reducing the risk of T2D by ~9%. 9

### Key messages

**What are the new findings?**
In addition to adding further support to the established position that a lifestyle that includes regular physical activity (PA) is associated with a good insulin sensitivity (SI) and exercise interventions can improve SI, evidence is growing for the following key findings:

- Aerobic exercise may increase SI without a measurable increase in VO₂ max or VO₂ peak.
- A dose effect may be evident, with greater exercise volumes and higher exercise intensities, including high intensity interval training (HIIT) or sprint interval training (SIT), producing greater benefits to SI.
- The combination of aerobic exercise training and REX may be more effective than either exercise mode alone.
- Exercise induced benefits may be augmented by appropriate dietary and feeding manipulations.
- Molecular research has identified key signalling molecules and proteins that are influenced by exercise and provide the link to resultant changes in SI.
- Evidence is accumulating for ceramides to be the causal link between obesity and a reduced SI.

**Practical recommendations**

- Despite the aforementioned general consensus, not all findings are consistent, and the specific details of the most efficacious forms of exercise/physical activity (PA) for improving or maintaining insulin sensitivity (SI) require further elucidation in order for exercise prescription to be optimised.
- Research needs to assess the interaction of dietary/feeding manipulations and exercise on SI and glycaemic control, as these may augment the beneficial outcomes of the interventions.
- Future research needs to consider the potential influence of exercise induced improvements to β cell function and increased muscle capillarisation, alongside the contribution of intramuscular changes that result in improved SI, GLUT4 availability and glycaemic control.
- Studies will also need to consider potential differences in the adaptations induced by different exercise modalities, aerobic versus REX; exercise intensities and volumes, including interval training (high intensity interval training (HIIT) and sprint interval training (SIT)); and differences in the adaptations of different fibre types.
- Likewise, the potential to adapt and improve SI is likely to be influenced by the basal state of the participants: with healthy participants, overweight/obese, prediabetic metabolic syndrome, and patients with diabetes all likely to differ in the magnitude of adaptation and improvement.
- Given the evident benefits of PA/exercise interventions for preventing diabetes, even among those with metabolic risk factors, studies aimed at identifying effective preventive strategies are paramount in order to prevent further increases in the prevalence of type 2 diabetes, particularly since only 10% of current clinical trials focus on prevention and only ~12% use behavioural interventions such as PA rather than drugs, which are the focus of ~63.1% of studies. 101

---

Physical activity has both immediate (acute) and longer-term effects on insulin sensitivity. The immediate effects are the direct result of a single exercise bout and may be evident during or for up to 72 hours postexercise. If repeated regularly these bouts produce additional long-term chronic improvements to SI, thereby providing superior baseline glycaemic control compared with that typically seen in less active individuals. In this healthy, physically active, 'trained' condition, the effects of individual exercise bouts may then produce further acute responses from this already elevated SI state and thereby promote optimal SI and glycaemic control. Some key issues around PA that are considered in recent literature include: the effects of manipulating the mode of exercise; the influence of exercise intensity and exercise duration; the potential benefits of high intensity interval training (HIIT); and the relative effects of the aforementioned on groups of different ages and at different levels of impaired SI. Other innovative strategies that have received recent attention include assessing whether the impact of exercise on SI is affected by whether it is undertaken in a fed or fasted state, and whether a short exercise bout (exercise snack) performed before meals is beneficial.

The purpose of this review is to provide an overview of the topic for those new to it and an update of recent developments for the established researcher.

METHODS

A literature search was undertaken using PubMed in November 2015, using search terms ‘Exercise’ OR ‘Physical activity’, AND ‘Insulin sensitivity’. This resulted in 10,185 articles, which were then limited to clinical trials (n=1672 articles), filtered using the terms ‘Human’ and limited to English language publications (n=1371). Reviews and key articles published in English since 2000 were used to present established knowledge and set the background context, while to identify recent updates the search was reduced to articles published after 2012: this resulted in 394 articles. The abstracts of these articles were then evaluated and studies included if the main focus was an exercise intervention or cross-sectional study of PA habits and not confounded by the inclusion of other interventions, such as drugs or diseases such as cancer. Studies were excluded if SI or other measures of glycaemic control were not included as an outcome measure. Titles were manually sorted and articles rejected if primary objectives were not exercise-based. They were then divided on the basis of whether they assessed the acute responses that occur during or immediately after a bout of PA, or the chronic adaptations that occur over a more prolonged period of time due to repeated exercise bouts—the training effects. A further search using the same search criteria was undertaken in July 2016 when the manuscript was undergoing minor revisions. This identified a further 80 articles that met the criteria of the search terms and the aforementioned manual sorting produced the resultant total of 53 recent articles which are summarised in tables 1 - 3.

In presenting this review, the authors acknowledge the growing evidence for the adverse effects of sedentary behaviour on diabetes risk and SI, and that this aspect of behaviour needs to be considered in the wider context of metabolic health. Likewise that exercise may benefit the SI of patients with a number of chronic disease conditions, such as cancers, but due to word limits, these scenarios were beyond the scope of this review.

**Molecular mechanisms for exercise-induced changes in SI and glycaemic control**

Glucose uptake into skeletal muscle occurs via facilitated diffusion down the diffusion gradient through the presence of the glucose transporter GLUT4 in the sarcolemma and T tubules. A single bout of exercise promotes acute increases in glucose uptake into the skeletal muscle, both during the exercise bout and for some hours postexercise. This increase occurs as a result of GLUT4 being translocated from intracellular sites to the sarcolemma and T tubules, thereby increasing the sites at which glucose can diffuse into the muscle. For a detailed review of the processes resulting in increased glucose uptake during exercise, readers are directed to that by Richter and Hargreaves.  

In summary, during a bout of exercise the increased contraction-stimulated glucose uptake is linked to increases in AMP-activated protein kinase (AMPK), which results in the phosphorylation of the Rab-GTPase-activating protein TBC1D1.  

This phosphorylation appears to inactivate the TBC1D1, although there is some suggestion that the TBC1D1 needs to be phosphorylated at both the AMPK and Akt sites for deactivation to occur. Since active TBC1D1 has an inhibitory effect, its deactivation enables GTP to react with Rab proteins on the GLUT4 vesicles, and as a consequence there is an increase in GLUT4 vesicle translocation and glucose uptake into the cell.

It appears that a slightly different pathway is used to regulate glucose uptake at rest, and involves TBC1D4 (also known as AS160), the parologue of TBC1D1. TBC1D4 is involved in the insulin stimulated regulation of GLUT4 translocation and glucose uptake in adipocytes and myocytes. Insulin promotes the phosphorylation of TBC1D4 causing its deactivation and thereby increasing GLUT4 activity. TBC1D4 is also involved in the regulation of glucose uptake postexercise, when increases in SI are associated with elevated intracellular kinase Akt, which results in the phosphorylation of TBC1D4. TBC1D4 has similar properties to TBC1D1 and produces similar effects, in that the active form TBC1D4 promotes the hydrolysis of GTP to GDP on Rab proteins, thereby preventing the translocation of GLUT4 to the cell membrane. ES, extended sprint; HIIT, high intensity interval training; LT, lactate threshold; OGTT, oral glucose tolerance test; SI, insulin sensitivity; SIT, sprint interval training.
when TCB1D4 is phosphorylated and deactivated the GTP reaction with Rab proteins increase GLUT4 translocation to the cell membrane and T tubules, which elevates SI. However, in contrast with TCB1D1, TCB1D4 appears to display a delayed response to exercise/contraction stimuli, with its deactivation exerting an effect postexercise rather than during exercise, an effect which has also been reported in rats. Regular exercise training may also result in chronic improvements in TBC1D4 phosphorylation and thereby increase basal SI.

Repeated exercise bouts (exercise-training) have been demonstrated to increases GLUT4 concentrations in populations with metabolic syndrome (MetS) and T2D, and these increases are associated with changes in SI. Such improvements are tissue specific, as exercise appears to improve skeletal muscle but not hepatic SI, nor insulin-stimulated glucose uptake in adipose tissue. In addition to this, the improvements are primarily located in the muscle fibres undertaking most of the work during the exercise.

Other molecules associated with the SI regulatory processes include insulin receptor substrate 1 (IRS-1) and IRS-2. While the precise roles of these receptor molecules require further elucidation, it is evident that they are activated by the insulin receptor tyrosine kinase and promote the phosphorylation/activation of Akt, thereby promoting glucose uptake into the cell. Reduced p-IRS-1 (ser632) phosphorylation has been reported in obese and obese insulin-resistant subjects, suggesting an association between lower concentrations of activated IRS-1 and impaired SI, whereas acute increases in IRS-1 phosphorylation have been demonstrated following a single 60 min bout of moderate intensity exercise (60% VO2 peak), suggesting an association with increased activation of IRS-1 and improved SI.

Obesity, excess lipid availability and SI

It is well established that obesity and an associated excess of available lipids results in a loss of SI in skeletal muscle, and this may be linked with impaired deactivation of TCB1D4. Paradoxically, while obesity increases intramyocellular triglyceride (IMTG) concentrations, so does endurance exercise training. Yet the skeletal muscles of obese sedentary individuals have a compromised SI, while those of well trained endurance athletes are highly insulin sensitive. Hence there must be a distinct molecular basis, other than differences in IMTG concentration to explain their contrasting SI characteristics. Diacylglycerols (DGs) and ceramides are lipid intermediates that have been proposed to explain this apparent paradox. However, while some studies have demonstrated that exercise can reduce DGs in previously inactive obese individuals, with a concomitant increase in SI, the causative role of DGs has been questioned as the muscles of endurance trained athletes have been shown to have nearly twice the DAG content of obese sedentary individuals and have a 50% higher DAG content than normal-weight sedentary individuals.

Conversely, evidence is accumulating for the view that ceramides (sphingolipid metabolites) may be the causal link between saturated fatty acid content (but not unsaturated fats) in skeletal muscle and impaired SI. In the acute phase, exercise has been demonstrated to increase serum ceramide, but these returned to basal levels 2 hours postexercise, while the sphingolipids measured in this study were not elevated during exercise but declined to below basal levels postexercise. However, exercise training has been demonstrated to reduce plasma ceramides and these changes are negatively correlated with increased SI. An explanation for the molecular link between ceramides and SI is through the presence of excess saturated FFA. This explanation suggests that the excess saturated FFA and associated high ceramide content inhibits Akt/PKB phosphorylation and activation by protein phosphatase 2A, thereby preventing the translocation of Akt/PKB from the cytoplasm to the membrane. This may then link to the aforementioned effects on the activation of other signalling molecules, leading to an impaired translocation of GLUT4 to the membrane.

Other molecular and physiological changes linked to exercise induced improvements to SI

Other molecules that may be linked to aerobic exercise induced changes in SI include intracellular adhesion molecule 1, C reactive protein and serum amyloid A, all of which have been shown to be associated with impaired SI, but are reduced by exercise and weight loss, thereby suggesting a link with vascular inflammation. Additionally, exercise stimulated increases in glycogen synthase activity have also been proposed as a factor that increases SI.

Another process through which SI may be improved is through the exercise training stimulated increase in skeletal muscle capillarisation. Prior et al. reported that increases in capillarisation correlated with improvements in insulin sensitivity following 6 months of aerobic exercise with weight loss in older adults with impaired glucose tolerance (IGT). This outcome was further investigated when after 6 months of training the participants followed a 2-week no aerobic exercise washout phase, in order to isolate the acute postexercise changes in SI from the training effects. The outcome of this was that while many of the aforementioned molecular factors returned to baseline after the washout, capillary density and SI remained elevated by 15% and 18%, respectively, providing evidence for a link between these two factors.

Additionally, while a good level of cardiorespiratory fitness (CRF) is associated with a reduced risk of poor insulin sensitivity, exercise interventions don’t always find an association between improvements in SI and
CRF (VO_{2\text{max}}). This may be because improvements in CRF are a result of a combination of both peripheral adaptations within the muscle and central cardiovascular adaptations, such as increases in cardiac output, the latter of which may not impact on SI directly.\(^{35}\)

An alternative mechanism by which exercise could improve glycaemic control, is via the enhancement of pancreatic \(\beta\) cell activity, which can become compromised as a consequence of overstimulation and excessive insulin secretion in response to a loss of SI. In support of this, it has been reported that exercise training plus weight loss can increase pancreatic \(\beta\) cell function in a linear dose-response manner in adults with prediabetes.\(^{24}\) In this study, relatively high exercise doses of >1900 kcal/week were used and the exercise intensity increased from 60%–65% HR_{max} during the first 4 weeks, to a relatively high 80%–85% HR_{max} for the following 8 weeks. Hence the intervention was of relatively high volume and intensity, which may not be feasible for most of the population in question. By comparison, Madsen \(et al^{36}\) reported improved \(\beta\) cell function in patients with T2D following more moderate volumes of exercise training in the form of high intensity interval training (HIIT), hence the exercise intensity may be key. However, Slentz \(et al^{37}\) have suggested that while both moderate and vigorous exercise are capable of stimulating improvements in \(\beta\) cell function as indicated by the Disposition Index (DI = SI x acute insulin response to glucose (AIRg)), they may do so via different mechanisms, since in their 8-month intervention study, large volumes of moderate intensity exercise produced a greater DI improvement than vigorous exercise, and achieved this with an improvement in SI but virtually no change in AIRg, while the vigorous exercise improved SI and resulted in a compensatory reduction in AIRg.

**Updates to acute SI responses to exercise**

Studies assessing the acute responses during or immediately following a single bout of aerobic exercise suggest that SI is improved by more than 50% for up to 72 hours after the last exercise bout.\(^{6}\) However, this acute improvement in SI is lost within 5 days after the last exercise bout, even in highly trained subjects.\(^{6}\)

Table 1 summarises recent studies that assessed acute responses to exercise on SI. Rynders \(et al^{3}\)'s study confirms the previously reported improvements in SI in patients with prediabetes of around 50% 1 hour after aerobic exercise.\(^{38}\) Likewise, Newsom \(et al^{39}\) reported an increase in SI in sedentary obese adults the day after moderate intensity exercise,\(^{39}\) indicating that the acute response was evident for some hours. However, whereas Rynders \(et al^{38}\) reported higher intensity exercise to produce greater improvements in SI (85% following high intensity exercise vs 51% following moderate intensity exercise), Newsom \(et al^{39}\) found that it did not. Indeed Newsom \(et al^{39}\) reported

that their lower intensity (50% VO_{2\text{peak}}) but longer duration bout of the same calorific cost was more effective as it resulted in a statistically significant 35% improvement in SI, whereas their bout at 65% VO_{2\text{peak}} only resulted in a 20% increase that was not statistically significant. The discrepancy between these studies may at least in part be due to the differences in the ‘higher’ exercise intensities used in these studies, with Newsom \(et al^{39}\)'s being of a more ‘moderate’ rather than ‘high’ intensity.

In a more recent study, Malin \(et al^{40}\) sought to identify the acute impact of exercise intensity on different components of insulin sensitivity and indicators of glycaemic control, including: glucose-stimulated insulin secretion (GSIS), skeletal muscle IR (SM_{IR}), hepatic IR (HOMA_{IR}) and adipose IR (ADIPOSE_{IR}). In their study they administered a 75 g OGTT 1 hour postexercise/control and in their analyses they assessed the relationship between the aforementioned measures and reported that exercise lowered SM_{IR} independently of exercise intensity, but that compared with controls, high intensity exercise (200 kcal cycle ergometer exercise bout at 75% of difference between lactate threshold and VO_{2\text{peak}}) increased HOMA_{IR} and ADIPOSE_{IR}; which may initially appear contradictory. However, since GSIS was not reduced postexercise and the DIs of the hepatic and adipose tissues were lowered with high intensity exercise, while that of muscle increased, it resulted in a lower postprandial blood glucose. Based on these findings the authors suggest that insulin secretion from the pancreas matches the combined requirements of these tissues and there is some communication between them to produce this outcome. They also suggest that the elevated HOMA_{IR} and ADIPOSE_{IR} may be beneficial postexercise, as it could promote greater glucose uptake into the skeletal muscle, in which IR is lower, and thereby more effectively promote the restoration of muscle glycogen postexercise.

The variable of exercise intensity is manipulated and taken to greater extremes through the prescription of ‘high-intensity interval training’ or sprint interval training (SIT), in which relatively short bursts of high intensity exercise are interspersed with lower intensity activity or rest recovery.\(^{41}\) Gibala \(et al^{42}\) propose that the term HIIT be used when repeated short bouts of exercise at intensities of between 80%HR_{max} and 100%HR_{max} are used, while protocols that involve repeated short bouts of maximal ‘all-out’ exercise at intensities greater than the work rate that elicits VO_{2\text{max}} be classified as SIT.

In the context of studies assessing the impact of short duration, high intensity exercise, including HIIT and SIT, Ortega \(et al^{43}\) found that while their high intensity intervals (four 30 s sprints), continuous low intensity (46% VO_{2\text{peak}}) and moderate intensity (77% VO_{2\text{peak}}) exercise bouts all improved insulin sensitivity in healthy men for at least 48 hours, the repeated sprints...
produced the greatest short-term effects 30 min postexercise. Similarly, the study by Terada et al\textsuperscript{41} reported that 60 min of HIIT (repetitions of 3 min at 40\% VO\textsubscript{2} peak and 1 min at 100\% VO\textsubscript{2} peak), reduced overnight and fasting glycaemia the day after the exercise by more than a bout of continuous moderate intensity exercise at 55\% of VO\textsubscript{2} peak. They also reported that exercising in a fasted state rather than ‘post-breakfast’ attenuated postprandial glycaemic increments; and compared with the control condition, HIIT in a fasted state produced significant improvements to: 24-hour mean glucose, fasting glucose, postprandial glycaemic increment, glycaemic variability and time spent in hyperglycaemia.

In comparison, Whyte et al compared four maximal 30 s sprints with 4.5 min recovery between each (SIT) and a single maximal extended sprint matched for work done.\textsuperscript{45} The day following exercise, the SIT session had failed to improve SI over a control (no exercise) condition, but the extended sprint had improved SI by 45\%. Hence the failure of SIT to improve SI in this study contradicts the findings of Ortega et al\textsuperscript{43} but raises the possibility of a single bout of high intensity exercise of relatively short duration (approximately 2–3 min) being sufficient stimulus to promote the regulatory processes underlying improvements in SI, and this requires further elucidation.

**Updates on the association between SI and PA—lifestyle studies**

Table 2 summarises the results from recent studies assessing potential links between a lifestyle involving regular PA and SI. Uemura et al\textsuperscript{36} survey confirms previous work that demonstrates a link between a lifestyle involving PA and better glycaemic control, as did Rosenberger et al\textsuperscript{47} who reported that a lifestyle involving regular walking and other activities reduced by 50\% the OR for MetS. Similarly, Caro et al\textsuperscript{48} reported a significantly lower (21 vs 46\%) prevalence of MetS in people who complied with the aerobic exercise guidelines of 30–60 min of moderate activity 5 days per week.

The importance of lifestyle is evident even in young people as a survey of children found that PA was negatively associated with markers of IR,\textsuperscript{49} and the study by Telford et al found that the prevalence of IR was reduced in primary school age children when PA was increased in school.\textsuperscript{50}

**Updates from studies assessing the effects of exercise training upon SI**

Exercise training studies generally report health benefits for the majority of participants, providing the exercise dose is of an appropriate intensity, frequency, duration and is undertaken for sufficient time.\textsuperscript{7,20} Meta-analyses and reviews indicate that regular aerobic exercise that complies with exercise prescription guidelines,\textsuperscript{51} increases SI by ~25–50\%.\textsuperscript{6,8} This training adaptation is likely induced by the increased activity of the muscle fibres, since low intensity aerobic activity, which primarily uses type 1 fibres, induces changes in type 1 fibres expressing myosin heavy chain (MHC) I, but not type 2 fibres (expressing MHC IIA or MHC IIX).\textsuperscript{12} If such adaptations are specific to the fibres that experience increased activity, then this presents the possibility of higher intensity exercise, which involves a greater recruitment of the type 2 fibres, inducing beneficial adaptations in both type 1 and type 2 fibres.

**Aerobic exercise interventions, including the assessment of the influence of exercise volume and intensity**

Table 3 summarises the results of recent studies assessing the effect of exercise interventions on SI. Studies consistently show that moderate aerobic exercise for 30 min or more, three or more times a week for 8 weeks or more improves SI and other markers of glycaemic control. This has been reported in a range of populations including women with diabetes,\textsuperscript{23,24} men and women with diabetes and IGT,\textsuperscript{33,34} obese men,\textsuperscript{35} obese women,\textsuperscript{36} obese and overweight postmenopausal women,\textsuperscript{38} obese adolescents,\textsuperscript{37,58} obese patients,\textsuperscript{59} sedentary moderately overweight young men,\textsuperscript{19,60} and adults with T2DM and non-alcoholic fatty liver disease.\textsuperscript{63}

A commonly advocated exercise prescription of three sessions per week of 30 min walking was used by Motahari-Tabari et al\textsuperscript{64} who reported improvements in the homoeostatic model assessment of insulin resistance (HOMA-IR), fasting plasma insulin and fasting glucose in women with T2D, following 8 weeks of this aerobic exercise regimen. Likewise, Herzig et al\textsuperscript{65} found that 60 min of walking, three times a week for 3 months in patients with prediabetes improved HOMA-IR, fasting and 2-hour insulin, despite no improvements in fasting 2-hour glucose or VO\textsubscript{2} max. The finding of an improvement in SI without an improvement in VO\textsubscript{2} max concurs with some previously mentioned studies.\textsuperscript{37}

Damirchi et al\textsuperscript{66} also demonstrated an improvement in insulin sensitivity in middle-aged men with MetS following a 6-week aerobic exercise programme of three sessions per week of 25–40 min walking or running at 50–60\% VO\textsubscript{2} peak, and also reported the interesting finding that this benefit was lost within 6 weeks of detraining. Solomon et al reported improvements in glucose-stimulated insulin secretion, but not SI in participants with T2D or IGT,\textsuperscript{67} and suggested that training-induced changes in β cell function may be a key determinant of training-induced improvements in glycaemic control. Additionally, Skleryk et al did not find any beneficial changes from 5 days a week of aerobic exercise at 65\% VO\textsubscript{2} peak in overweight/obese sedentary men,\textsuperscript{55} but their exercise intervention was only for 2 weeks and may not have been of sufficient duration to induce detectable changes. Likewise,

<tr>
<td>Uemura et al⁴⁶</td>
<td>Five hundred and eighteen eligible subjects (380 men and 138 women) who attended the Tokushima Prefectural General Health Checkup Center.</td>
<td>Survey.</td>
<td>Questionnaire on lifestyle characteristics, including leisure-time exercise and daily non-exercise activities.</td>
<td>Subjects with longer durations of daily non-sedentary activities had significantly lower adjusted ORs for MetS. Daily non-sedentary activities were associated with lower HOMA-IR.</td>
<td>A lifestyle involving greater time spent in non-sedentary activities reduced the risk of IR.</td>
</tr>
<tr>
<td>Rosenberger et al⁴⁷</td>
<td>Three hundred and one overweight/obese patients with prediabetes.</td>
<td>Survey of PA habits.</td>
<td>Participants reported walking and other activities, and were assessed for factors associated with MetS. Participants were categorised as those with and those without MetS.</td>
<td>Eighteen per cent of subjects with MetS reported at least 150 min of activity minutes per week compared with 29.8% of those without MetS. The odds of MetS was lower with greater activity minutes.</td>
<td>Meeting PA goals of 150 min/week, reduced MetS odds in overweight/obese adults with prediabetes.</td>
</tr>
<tr>
<td>Caro et al⁴⁸</td>
<td>One hundred and one adults with no personal history of disease aged 30–70 years.</td>
<td>A cross-sectional, observational study in an adult population. Participants were age-matched and sex-matched for comparison.</td>
<td>Participants were classified into: (1) those who undertook regular exercise of 30–60 min of moderate physical exercise 5 days per week, and (2) non-exercising controls who exhibited a sedentary lifestyle.</td>
<td>Indicators of fasting plasma insulin levels HOMA-IR were significantly lower in the regular PA group. Prevalence rates of MetS were 20.7% and 45.8% in the regular PA and sedentary groups, respectively.</td>
<td>Moderate regular PA is associated with higher SI.</td>
</tr>
<tr>
<td>Jiménez-Pavón et al⁴⁹</td>
<td>One thousand and fifty-three boys and girls, aged 12.5–17.5 years.</td>
<td>A cross-sectional study in a school setting.</td>
<td>PA was assessed via accelerometer; CRF assessed via a 20m shuttle run test. Fasting insulin and glucose concentrations were measured. The HOMA-IR and quantitative SI index were calculated.</td>
<td>In men, VPA was negatively associated with markers of resistance (IR) after adjusting for confounders including waist circumference. In women moderate PA, moderate PA to VPA, and average PA were negatively associated with markers of IR after adjusting for confounders. When the sample was segmented by CRF levels, all the PA intensities were significantly negatively associated with the markers of IR in women with low CRF but not in those with middle-high CRF after adjusting for confounders.</td>
<td>The findings suggest that PA is negatively associated with markers of IR after adjusting for confounders including total and central body fat in both sexes. This relationship is modified by the CRF levels, which are especially important in those women with low CRF. Preventive strategies should focus on increasing the volume of PA and on enhancing CRF through VPA.</td>

<tr>
<td>Telford <em>et al</em></td>
<td>Seven hundred and eight primary school children, mean age 8.1±0.35 years.</td>
<td>Four-year cluster-randomised intervention study into the effects of specialists versus non-specialists delivering physical education classes.</td>
<td>The intervention involved the employment of specialist physical education teachers to deliver PE classes (intervention) in primary schools, rather than delivery by generalist primary teachers (control).</td>
<td>The PE classes delivered by the PE specialists involved more fitness work than the control PE classes delivered by primary generalists (7 min vs 1 min) and more moderate PA (17 min vs 10 min, respectively). There were no differences at baseline, but by grade 6, the intervention had lowered the prevalence of IR by 14% in the boys and by 9% in the girls, also the percentage of children with IR &gt; 3 (a cut-off point for metabolic risk) was lower in the intervention than in the control group (combined, 22% vs 31%; boys, 12% vs 21%; girls, 32% vs 40%).</td>
<td>Specialist-taught primary school PE increased physical activity in PE classes, and was associated with a lower prevalence of IR in community-based children.</td>

<tr>
<td>Stuart et al15</td>
<td>Eleven participants with MetS and seven non-diabetic, sedentary controls.</td>
<td>Exercise intervention. Preintervention versus postintervention comparison.</td>
<td>Eight weeks of increasing intensity stationary cycle training.</td>
<td>Cycle training without weight loss did not change IR in MetS subjects or sedentary controls. Muscle insulin receptor expression increased in both MetS and sedentary groups, while GLUT4 expression also increased in the MetS subjects. The excess phosphorylation of IRS-1 at Ser337 in MetS muscle tended to increase further after training in spite of a decrease in total IRS-1.</td>
<td>In the absence of weight loss, the cycle training of MetS subjects increased the expression of insulin receptors and GLUT4 in muscle but did not decrease the IR.</td>
</tr>
<tr>
<td>Malin et al18</td>
<td>Twenty-four older, obese adults with IFG and/or IGT.</td>
<td>Exercise intervention.</td>
<td>Twelve weeks of exercise (60 min/day, 5 days/week at ~85% HRmax).</td>
<td>Exercise increased clamp-derived peripheral and hepatic SI more in adults with IFG or IGT alone than with IFG + IGT.</td>
<td>Exercise increased peripheral but not hepatic SI.</td>
</tr>
<tr>
<td>Reichkendler et al19</td>
<td>Sixty-one, healthy, sedentary, moderately overweight young men.</td>
<td>Randomised, controlled trial.</td>
<td>Moderate (300 kcal/day) or high (600 kcal/day) physical exercise for 11 weeks, versus sedentary living (control). Pretraining and post-training, insulin-stimulated glucose uptake was assessed in five individual femoral muscle groups and four different adipose tissue regions.</td>
<td>Aerobic exercise training increased insulin-stimulated glucose uptake in skeletal muscle but not in adipose tissue.</td>
<td>Aerobic exercise training enhances glucose uptake in muscle but not adipose tissues, indicating a differential effect on these tissues.</td>
</tr>
<tr>
<td>Prior et al12</td>
<td>Sixteen sedentary overweight, obese, older men and women, with IGT</td>
<td>Preintervention versus postintervention comparison.</td>
<td>Six months of aerobic exercise and weight loss. Three sessions a week progressing from 20 min at 50% HRR to 45 min at 85% of HRR.</td>
<td>Hyperinsulinaemic-euglycaemic clamp and OGTT. Capillary density was measured via biopsies of the vastus lateralis.</td>
<td>Insulin sensitivity increased and 120 min postprandial glucose was lower postintervention. These changes were associated with increases in capillary density.</td>

<tr>
<td>Malin et al&lt;sup&gt;34&lt;/sup&gt;</td>
<td>Thirty-five older obese adults with prediabetes.</td>
<td>Exercise intervention.</td>
<td>Progressive 12-week exercise intervention (60 min at ~85% HR&lt;sub&gt;max&lt;/sub&gt; 5 days/week).</td>
<td>Exercise increased first-phase and second-phase DI; β cell function = glucose-stimulated insulin secretion ( \times ) clamp-derived SI.</td>
<td>Exercise training plus weight loss increased pancreatic β cell function in a linear dose-response manner in adults with prediabetes. Relatively high exercise doses (&gt;2000 kcal/week) may be necessary to enhance β cell function in adults with poor insulin secretion capacity.</td>
</tr>
<tr>
<td>Madsen et al&lt;sup&gt;36&lt;/sup&gt;</td>
<td>Ten, non-active patients with T2D (56±2 years) and 13 matched healthy participants.</td>
<td>Preintervention versus postintervention comparison.</td>
<td>Three sessions per week of HIIT (10 × 60 s) for 8 weeks for both patients with T2D and healthy participants. Glycaemic control was assessed using HOMA-IR and β cell function assessed.</td>
<td>Patients with T2D displayed significant improvements in HOMA-IR and β cell function. The healthy group, who displayed superior HOMA-IR and β cell function results at baseline, exhibited no change in these measures, which was not unexpected given their baseline values.</td>
<td>HIIT was effective in improving HOMA-IR and β cell function in patients with T2D.</td>
</tr>
<tr>
<td>Brennan et al&lt;sup&gt;35&lt;/sup&gt;</td>
<td>Seventy-seven sedentary, obese men and women.</td>
<td>Repeated measures, intervention versus control condition.</td>
<td>Three to four months of aerobic exercise versus control</td>
<td>Hyperinsulinaemic-euglycaemic clamp and VO&lt;sub&gt;2 peak&lt;/sub&gt;.</td>
<td>Changes to insulin sensitivity were not associated with changes to VO&lt;sub&gt;2 peak&lt;/sub&gt;.</td>
</tr>
<tr>
<td>de Sousa et al&lt;sup&gt;36&lt;/sup&gt;</td>
<td>Forty-four patients with T2D, aged 48–68 years (27 women, 17 men).</td>
<td>Randomised trial: diet versus football training plus diet.</td>
<td>Football training: 3 × 40 min/week for 12 weeks.</td>
<td>Football training plus diet group displayed improvements in HOMA-IR, whereas diet alone did not.</td>
<td>Football training plus diet was potentially better at preventing T2D complications than diet alone. It was also more effective than diet alone at improving other markers of metabolic and cardiovascular health, such as blood lipid profile and CRF.</td>
</tr>
<tr>
<td>Motahari-Tabari, et al&lt;sup&gt;52&lt;/sup&gt;</td>
<td>Fifty-three women with T2D.</td>
<td>Randomised clinical trial: exercise versus control.</td>
<td>Thirty minutes at a maximum intensity of 60% increase in heart rate, three times a week for 8 weeks.</td>
<td>HOMA-IR improved and fasting plasma glucose and insulin were lowered.</td>
<td>Exercise was effective at improving SI.</td>
</tr>

<tr>
<td>Ryan et al&lt;sup&gt;53&lt;/sup&gt;</td>
<td>Seventy-seven overweight and obese, sedentary, postmenopausal women.</td>
<td>Prospective controlled study.</td>
<td>Six months of: ‘aerobic exercise (3 days/week) + weight loss’ versus ‘weight loss without exercise’.</td>
<td>IR decreased in both groups. Glucose utilisation increased by 10% with ‘aerobic exercise + weight loss’ versus ‘weight loss without exercise’. No statistically significant difference in changes to IR between ‘aerobic exercise + weight loss’ versus ‘weight loss without exercise’. However, exercise benefited other markers of metabolic health.</td>
<td></td>
</tr>
<tr>
<td>Mitranun et al&lt;sup&gt;54&lt;/sup&gt;</td>
<td>Forty-three participants with T2D.</td>
<td>Randomised controlled trial.</td>
<td>Sedentary (control) versus continuous exercise versus INT. For 30 min/day and 40 min/day, three times/week for 12 weeks.</td>
<td>Fasting blood glucose levels decreased in both exercise groups. Glycosylated haemoglobin levels decreased only in the interval training INT group. Both continuous training and INT were effective in improving glycaemic control, but the INT programme appears to confer greater improvements.</td>
<td></td>
</tr>
<tr>
<td>Skleyk et al&lt;sup&gt;55&lt;/sup&gt;</td>
<td>Sixteen sedentary, obese men.</td>
<td>Exercise intervention.</td>
<td>Two weeks of reduced-volume SIT (three sessions of 8–12 × 10 s sprints/week) compared with TER (5 × 30 min sessions at 85% peak oxygen consumption/week).</td>
<td>HOMA-IR, AS160 phosphorylation and COX II, COX IV, GLUT-4, Nur77 and SIRT1 protein expression assessed at baseline and approximately 72 hours after the final training bout were unaltered in either group. Two weeks of reduced-volume SIT or TER did not elicit any measurable metabolic adaptations in previously sedentary, obese men.</td>
<td></td>
</tr>
<tr>
<td>Trachta et al&lt;sup&gt;56&lt;/sup&gt;</td>
<td>Fifteen obese women.</td>
<td>Intervention with comparison group comprising ‘healthy’ lean subjects who did not undertake the exercise intervention.</td>
<td>Three-month exercise programme consisting of 30 min of aerobic exercise, three times a week.</td>
<td>HOMA-IR improved in the obese group.</td>
<td></td>
</tr>
<tr>
<td>Many et al&lt;sup&gt;57&lt;/sup&gt;</td>
<td>Eleven morbidly obese minority adolescents (BMI 41.4±1.8 kg/m&lt;sup&gt;2&lt;/sup&gt;)</td>
<td>Exercise intervention.</td>
<td>Eight weeks of aerobic exercise training (~180 min/week at 40–55% VO&lt;sub&gt;2&lt;/sub&gt; peak). Preintervention and postintervention, SI and inflammatory markers were assessed.</td>
<td>Insulin action improved in response to training, as indicated by a ~37% increase in SI. This study supports the efficacy of exercise training interventions on improving MetS features in morbidly obese minority youth.</td>

<td>Fifty-three women with T2D.</td>
<td>Exercise intervention versus non-exercise control condition.</td>
<td>Eight weeks of walking for 30 min three times a week.</td>
<td>Exercise improved HOMA-IR, fasting plasma insulin and glucose.</td>
<td>The exercise intervention was effective in lowering plasma glucose, insulin levels and IR.</td>
</tr>
<tr>
<td>Herzig et al&lt;sup&gt;65&lt;/sup&gt;</td>
<td>One hundred and thirteen men and women with prediabetes.</td>
<td>Exercise intervention versus non-exercise control condition.</td>
<td>Three sessions of 60 min walking per week, for 3 months versus non-exercise control.</td>
<td>The exercise intervention improved HOMA-IR, fasting insulin and glucose.</td>
<td>Compared with controls, the exercise group improved HOMA-IR and fasting insulin, but did not improve VO&lt;sub&gt;2&lt;/sub&gt;max or fasting glucose.</td>
</tr>
<tr>
<td>Damirchi et al&lt;sup&gt;66&lt;/sup&gt;</td>
<td>Twenty-one middle-aged men with MetS.</td>
<td>Exercise intervention versus control condition.</td>
<td>Six weeks of aerobic exercise; three sessions per week, for 25–40 min of walking or running at 50–60% VO&lt;sub&gt;2&lt;/sub&gt;peak. Followed by 6 weeks of detraining.</td>
<td>HOMA-IR improved after 6 weeks of training, but had returned to baseline after 6 weeks of detraining.</td>
<td>Regular exercise improved insulin sensitivity, but needs to be maintained as SI is lost if regular exercise ceases.</td>
</tr>
<tr>
<td>Solomon et al&lt;sup&gt;67&lt;/sup&gt;</td>
<td>One hundred and five participants, with IGT or T2D.</td>
<td>Observational clinical study.</td>
<td>Twelve to 16 weeks of aerobic exercise training.</td>
<td>Glycosylated haemoglobin, fasting glucose and 2-hour OGTT were improved postintervention in 69%, 62% and 68% of subjects, respectively, while SI improved in 90% of the participants.</td>
<td>Training-induced changes in glycaemic control were related to changes in glucose-stimulated insulin secretion, but not SI. Training-induced changes in β cell function may be a key determinant of training-induced improvements in glycaemic control.</td>
</tr>
<tr>
<td>Grieco et al&lt;sup&gt;68&lt;/sup&gt;</td>
<td>Forty-five healthy recreationally active young adults.</td>
<td>Randomised controlled trial.</td>
<td>Six-week exercise intervention. Four groups: moderate intensity (50% HRR), vigorous intensity (75% HRR), maximal intensity intervals (85/50% HRR) and non-exercising control group.</td>
<td>There were no significant changes in insulin effectiveness (HOMA and QUICKI) in any exercise group.</td>
<td>The exercise intervention did not significantly affect insulin effectiveness in a young adult population as assessed by HOMA or QUICKI.</td>
</tr>

</tr>
<tr>
<td>Chen et al&lt;sup&gt;69&lt;/sup&gt;</td>
<td>Twenty-three men and women with MetS and 87 men and women without MetS; mean age 48 and 49 years, respectively.</td>
<td>Pre-exercise versus postexercise intervention comparison.</td>
<td>Three months home-based exercise programme of three x 30-min sessions per week at a moderate intensity of either ‘stepper’ or ‘cardio-dance’.</td>
<td>HOMA-IR was maintained in the non-MetS group (1.8 vs 1.9), but deteriorated in the MetS group (3.6 vs 4.3).</td>
<td>The authors reported that 72% of the non-MetS group but only 39% of the MetS group achieved the minimum exercise compliance, and suggested that this may have affected the poor outcome in the MetS group.</td>
</tr>
<tr>
<td>Duvivier et al&lt;sup&gt;74&lt;/sup&gt;</td>
<td>Eighteen healthy subjects.</td>
<td>Cross-over design to compare daily regimens of activity and exercise.</td>
<td>Four days of each of the following regimens: (1) 14 hours/day sitting, (2) 13 hours/day sitting +1 hour/day vigorous exercise, (3) 8 hours/day sitting +4 hours/day walking +2 hours/day standing.</td>
<td>OGTTs were undertaken the morning after 4 days on each regimen. AUC for insulin was lower following the walking and standing regimen compared with the others.</td>
<td>Reducing sitting time by walking and standing was more effective than 1 hour of vigorous exercise in maintaining SI.</td>
</tr>
<tr>
<td>Earnest et al&lt;sup&gt;75&lt;/sup&gt;</td>
<td>Men at risk for IR.</td>
<td>Randomised, controlled, exercise intervention trial.</td>
<td>Three months of eucaloric (12 kcal/kg/week) steady state AER compared with INT.</td>
<td>Twenty-four-hour and 72-hour postexercise fasting OGTT improved. HOMA-IR was improved with INT and AER. Stratification of participants based on pretraining values for HOMA-IR revealed that both low and high HOMA-IR participants demonstrated significant reductions with INT, whereas only high HOMA-IR showed significant improvements with AER.</td>
<td>Eucaloric AER and INT appear to affect fasting glucose OGTT similarly. Both INT and AER benefited those with high HOMA-IR, while INT also benefited those with low HOMA-IR, thereby suggesting that INT may have a greater impact by benefiting across a wider spectrum of HOMA-IR.</td>
</tr>

<tr>
<td>Gillen et al&lt;sup&gt;76&lt;/sup&gt;</td>
<td>Twenty-five sedentary men (27±8 years).</td>
<td>Randomised control trial.</td>
<td>For 12 weeks, three sessions per week of either: (1) SIT (3 × 20 s maximal sprint, interspersed with 2 min cycling recovery at 50 W), (2) 45 min of moderate intensity cycling at ~75% HR&lt;sub&gt;max&lt;/sub&gt; (~110W) or (3) non-exercise control. SI was assessed via intravenous glucose tolerance tests.</td>
<td>Both exercise regimens produced significant and similar improvements in SI as measured via intravenous glucose tolerance tests performed before and 72 hours postexercise. Likewise VO&lt;sub&gt;2&lt;/sub&gt; peak improved (~19%) in both exercise groups, as did skeletal muscle mitochondrial content. There were no statistically significant changes in the control group.</td>
<td>SIT produced similar fitness and SI improvements to prolonged moderate intensity exercise, despite requiring a fivefold lower exercise volume and time commitment.</td>
</tr>
<tr>
<td>Shepherd et al&lt;sup&gt;77&lt;/sup&gt;</td>
<td>Ninety previously inactive volunteers.</td>
<td>Randomised control trial.</td>
<td>Ten weeks, three sessions per week of either: (1) HIIT (15–60 s with target HR &gt;90% HR&lt;sub&gt;max&lt;/sub&gt;, with 45–120 s active recovery for a total of 18–25 min, including warm-up) or (2) 30–45 min continuous exercise at an intensity ~70% HR&lt;sub&gt;max&lt;/sub&gt;.</td>
<td>HOMA improved in both groups, but was achieved with less time commitment and greater adherence in the HIIT group.</td>
<td>HIIT may provide a time-efficient alternative to continuous moderate intensity exercise.</td>
</tr>
<tr>
<td>Arad et al&lt;sup&gt;80&lt;/sup&gt;</td>
<td>Twenty-eight overweight/obese African American women.</td>
<td>Randomised control trial, with diet determined to maintain body weight. Exercise intervention n=14; control n=14.</td>
<td>For 14-weeks, three sessions per week of HIIT (4 × 30–60s at 75–90% HR with 180–210s at 50% HR between high intensity bouts) or non-exercise control. SI was assessed using 3-hour euglycaemic-hyperinsulinaemic clamp.</td>
<td>While some parameters of exercise metabolism improved, there were no improvements in SI compared with the control group.</td>
<td>HIIT did not improve SI when weight was maintained.</td>
</tr>
<tr>
<td>Lanzi et al&lt;sup&gt;81&lt;/sup&gt;</td>
<td>Nineteen obese men.</td>
<td>Randomised control trial.</td>
<td>Two-week exercise intervention, four sessions per week of either: (1) HIIT (10 × 60 s at 90% HR&lt;sub&gt;max&lt;/sub&gt;, with 60s recovery) or (2) 40–50 min continuous exercise at an intensity identified as that eliciting Fat&lt;sub&gt;max&lt;/sub&gt;.</td>
<td>Aerobic fitness improved in both groups, but HOMA2-IR only improved in the Fat&lt;sub&gt;max&lt;/sub&gt; group.</td>
<td>In the short term (2 weeks) exercise training of a continuous moderate intensity (Fat&lt;sub&gt;max&lt;/sub&gt;) was more effective than HIIT at improving glycaemic control.</td>
</tr>

Grieco et al’s study on recreationally active young adults did not change insulin effectiveness, although, given that the participants were already recreationally active it may be that their prestudy values were not sufficiently poor to be changed by the relatively short 6-week intervention.

Chen et al’s study also produced results that were not in accordance with similar studies and they suggested that this may have been due to participants’ lack of compliance and exercise intensity, with their non-MetS group attaining greater compliance and thereby maintaining their SI, while their MetS group displayed poorer compliance, which may have contributed to their decline in SI.

One exercise variable that is subject to manipulation in exercise interventions is that of exercise volume, and in general, studies that have examined a possible dose response report additional benefits from higher exercise doses (>1900 kcal/week), with increases in SI and improved β cell function in adults with prediabetes. While such levels of activity may be desirable, compliance is often low even for much lower exercise volumes and for those who are unable to meet these levels it is evident that much of the health benefit is attained from an exercise dose of only ~1900 kcal/week or even less, with only minor additional benefits to fitness, body fat and insulin sensitivity when exercising for 600 kcal/day compared with 300 kcal/day. Indeed the commonly prescribed dose of 5 × 30 min of moderate intensity exercise/week, which is reported on numerous occasions to be effective, would be around 475–950 kcal/week.

Another exercise variable that is receiving attention in the research is that of exercise intensity, as many of the adaptations that play a role in the exercise-induced increases in SI display a response that is related to the intensity of the activity. For example, while low-intensity training such as walking for 30 min, 3–4 days per week, for 6 months improves markers of glycaemic control (such as ‘area under the curve’ (AUC) for insulin), a further 6 months of higher intensity exercise (jogging 3–4 days per week for 6 months) elicits substantially greater improvements. Some reviews suggest that higher intensity exercise (>75% of VO₂ peak) is more efficacious than lower intensity (<60% of VO₂ peak). However, these findings are equivocal as others have reported that lower intensity activity, such as prolonged bouts of standing and walking are more effective than vigorous exercise of the equivalent energy expenditure in improving insulin sensitivity as indicated by OGTTs. Hence in the context of sustained bouts of continuous exercise the issue of the relative importance of exercise volume in terms of duration or total caloric cost of the exercise, versus the intensity of the exercise remains to be resolved.

Interval training (HIIT and SIT) that uses repeated brief bouts of exercise at intensities that are greater than those used in exercise sessions involving a more

prolonged single continuous exercise bout has been demonstrated to induce significant increases in GLUT4 protein (up to 200%) and SI (25%–35%) with the overall outcomes indicating comparable improvements in SI compared with moderate intensity continuous exercise training, despite it involving substantially less time commitment and reduced total exercise volume. Additionally, Earnest et al found INT to benefit patients with low HOMAIR as well as patients with high HOMAIR, whereas moderate intensity aerobic exercise only benefited the patients with high HOMAIR. Hence interval training could be beneficial to both, and for those with relatively mild IR it may be more effective in preventing further decline and/or restoring SI. As an extension of this, it may be speculated that HIIT could be a more effective preventative exercise regimen for asymptomatic healthy individuals. Furthermore, Madsen et al reported that HIIT improved both HOMA-IR and β cell function in patients with T2D, hence it could be beneficial across the IR spectrum.

Shepherd et al investigated the efficacy of HIIT in a ‘gym-setting’ with 90 previously inactive volunteers. In this study they reported that both HIIT and moderate intensity exercise improved SI, but HIIT achieved this with less than half the time commitment and greater adherence. Such findings are important given that a ‘lack of time’ remains the most commonly cited barrier to regular exercise participation. This, combined with reports of greater enjoyment when compared with sessions undertaken at a constant high intensity, is likely to improve compliance, although the higher intensity of the exercise may make it unsuitable for some ‘at risk’ individuals with cardiovascular issues. However, not all studies have reported HIIT to improve insulin sensitivity, including those of Arad et al in which overweight/obese African American women undertook 14 weeks of HIIT (three sessions a week), while maintaining a stable weight and that of Lanzi et al in which moderate intensity exercise was more effective that HIIT in improving HOMA2-IR in obese men, although the exercise intervention for this later study was only 2 weeks. The complexity of the issue is exemplified in the findings of studies such as that of Fisher et al in which both HIIT and moderate intensity exercise improved SI, as determined by an OGTT, but did not improve IR as determined by HOMA-IR (fasting insulin (μU/ml) x fasting glucose (mmol/L)). In another work, while Matsuo et al reported beneficial trends in HOMA-IR following HIIT as well as moderate intensity exercise, the results only reached statistical significance when the participants went on to follow a 4-week low-calorie diet.

**Effects of resistance training upon SI**

While much of the early research into exercise and SI has focused on aerobic exercise, recent exercise interventions using resistance training (REX) have demonstrated that this mode of exercise can also improve indicators of glycaemic control in a variety of populations, including older overweight individuals with prediabetes and postmenopausal women. However, the training adaptations may not always change all indicators of glycaemic control as Eikenberg et al found that twice weekly resistance training for 12 weeks improved 2-hour OGTT results in their participants who commenced the study with IGT and impaired fasting glucose (IFG), but not in those who commenced with IFG without IGT. Likewise, REX did not alter fasting glucose concentrations, AUC or ISI.

At a molecular level, REX consisting of two to three sessions per week for 8–26 weeks, can increase GLUT4 concentrations and translocation by 30–70%, and enhance SI by 10–48%. Some studies suggest that these improvements could be partially dependent on the training stimulus increasing muscle mass, as well as qualitative changes within the muscle, with the metabolic adaptations potentially involving changes in the type 2A fibres that are likely to be recruited during REX, as well as type 1 fibres. As indicated elsewhere these adaptations may not be homogenic between fibre types or exercise modalities. Furthermore, since both endurance exercise and REX increase SI, it is possible that a combination of these two training modalities could have additive benefits, particularly if the molecular targets of these activities differ. Indeed the study by Inoue et al found that the combination of aerobic plus resistance exercise was better than aerobic exercise alone at improving insulin sensitivity in postpubertal obese adolescents. These results concur with the findings of Dámaso et al whose findings also suggested that the combination of aerobic and resistance training had better metabolic outcomes than aerobic training (AER) alone for obese adolescents. Furthermore, Nikesresht et al compared the efficacy of aerobic INT and resistance training and found them to be equally effective in reducing IR and fasting insulin levels, but suggested that the aerobic programme had better anti-inflammatory effects. Consequently the findings of various studies have contributed towards ‘evidence-based’ exercise recommendations now including both aerobic and REX guidelines for healthy individuals.

A recent study by Conceição et al adds further support to the incorporation of REX to improve glycaemic control in postmenopausal women. However, the influence of changes in muscle mass through resistance exercise requires further elucidation since Molstead et al reported improvements in fasting insulin, 2-hour insulin and the AUC for insulin in patients with IGT or T2D who had no increase in muscle mass, while Mavros et al reported that in their study the improvements in SI (HOMA2-IR) in older patients with T2DM were associated with changes in skeletal muscle mass. Hence further work is required.
to elucidate the impact of quantitative (mass) and qualitative changes to the skeletal musculature on SI. Bacchi et al in their study on patients with T2DM and non-alcoholic fatty liver disease, found that both REX and aerobic exercise improved SI and reduced hepatic fat content. Likewise, as previously mentioned, Nikseresht et al65 found resistance training to be as effective as aerobic INT in reducing IR in obese middle-aged men. Whereas Lee et al did not find REX to improve SI in obese adolescent girls, while aerobic exercise did.62

Circuit training is another variation of exercise mode, including elements of resistance training and HIIT, as the exercise sessions typically involve brief bouts of high intensity muscular resistance exercise interspersed with rest periods. In studies involving obese 10–17-year-olds with prediabetes, it has been demonstrated to improve SI when undertaken with a dietary intervention.63

The effect of exercising in a fed or fasted state and other exercise-food manipulations

In 2010, Van Proeyen et al64 published a study in which they fed their participants a fat rich (50% of kcal) hypercaloric (+30% kcal/day) diet for 6 weeks. During this time the participants exercised (cycling and running) four times a week (2 × 60 min and 2 × 90 min). Some of these participants exercised in a fasted state, while others ate a carbohydrate rich breakfast ~90 min before the exercise, as well as receiving a carbohydrate drink during the exercise session (CHO-Fed). There was also a non-exercise control group. The overall outcome of this was that the group who trained in a fasted state did not increase their body mass, unlike those in the control and CHO-fed groups. The fasted group also displayed superior improvements in SI compared with the control group, whereas the CHO-fed group did not. Furthermore the fasted group showed greater increases in GLUT4, and whereas the CHO-fed group did not. Furthermore the fasted group also displayed superior improvements in SI compared with the control group, while exercising when carbohydrate had been recently ingested. The enhancements of these training effects appear to concur with the improved acute responses when exercising in a fasted state.44 In related work, as mentioned previously, Matsuo et al65 reported that beneficial changes in HOMA-IR were enhanced when the participants undertook a low-calorie diet for 4 weeks following the exercise intervention, even though the exercise intervention had ceased, thus further highlighting the interaction between exercise and diet in influencing SI.

Other exercise-feeding manipulations that have received recent attention include undertaking exercise before meals—‘exercise snacks’.66 From which, findings indicate that brief bouts of exercise (6 × 1 min incline walking at 90% HRmax) 30 min before main meals improved glycaemic control in individuals with IR.

Exercise, SI and changes to body mass

Numerous studies have reported that exercise induced improvements in SI are independent of changes to body composition or diet induced weight loss, and that the benefits of exercise and weight loss are additive,5 6 as reported by de Sousa et al66 who found football training coupled with weight loss improved insulin sensitivity and blood lipid profile, whereas weight loss alone did not. However these findings are not unequivocal as some studies report weight loss to be the key component to improving SI, for example, Stuart et al found that Aer without weight loss did not improve SI in individuals with MetS, whereas exercise with weight loss did, thereby implying that the main influence on improving SI was weight loss rather than exercise.15 Similarly, Trussardi Fayhn et al found that exercise training did not add to the effect that weight loss had on improving SI in obese individuals.97

By way of comparison, several recent studies suggest that the combination of exercise training and diet is more effective than diet alone in improving SI, and even when the additional benefits of exercise plus diet versus diet alone were modest,62 94 the inclusion of exercise improved other markers of metabolic health.92 Likewise, Mavros et al reported that improvements in metabolic health in older patients with T2DM were mediated through improvements in body composition only if they were achieved through high intensity progressive REX.95

Non-responders and adverse responders to exercise interventions

While there is unequivocal evidence for PA improving population and participant group mean values, indicating positive changes in the majority of participants within the data, it is evident that there is considerable variation in the magnitude of response to exercise interventions within the population: with some individuals displaying considerably greater changes in a variety of health-related outcome measures than others, despite adhering to the same exercise regimen.68 Additionally, the magnitude of change in one factor, such as VO2 peak, is not necessarily associated with the magnitude of change in another factor. For example, in the HART-D study, a 9-month exercise training intervention for patients with T2DM,99 57% of participants displayed an increase in their peak oxygen uptake (VO2 peak), while the remaining 43% exhibited no change. Of those who did show an improvement, only around two-thirds increased their VO2 peak by >5% (high responders to exercise), and a third displayed <5% increase (low responders to exercise). Yet despite this disparity in the magnitude of change in aerobic capacity, the exercise intervention
induced similar improvements in HbA1c and body composition (reduction % body fat) in both responders and non-responders for VO$_2$ peak. Hence the improvements in glycaemic control were associated with participating in the exercise training, but were not associated with changes to aerobic fitness, expressed as percentage improvement in VO$_2$ peak, which was also a finding of the study by Herzig.\textsuperscript{65}

Furthermore, there is also evidence that a minority of the population may respond adversely to exercise intervention, as reported in the HERITAGE study on 1687 men and women, in which 126 (8.4%) displayed an adverse change (increase $>3.5$ mU/L) in fasting insulin.\textsuperscript{100} The underlying reasons for these adverse changes are unknown, but their elucidation may further the cause of individualised exercise prescription.\textsuperscript{100}

**CONCLUSION**

Recently (published 2013-2016) studies involving PA confirm previous research findings of its efficacy in improving SI. A lifestyle incorporating aerobic exercise and/or PA that complies with the guidelines of being of moderate intensity for at least 30 min on 3–5 days per week, is associated with improved SI and glycaemic control. Acute improvements in SI (2–72 hours postexercise) occur after a single bout of exercise and chronic adaptations are evident from training studies involving interventions undertaken for at least 8 weeks. The benefits of PA/exercise are evident across all ages from children to older adults, including those categorised as asymptomatic/healthy, prediabetic/MetS, and patients with T2DM. However, the findings are not unequivocal and even within studies not all indicators of insulin sensitivity and glycaemic control display improvement. Indeed, even with increases in the expression of IRS-1 and GLUT4, decreases in IR are not guaranteed.\textsuperscript{69} A dose response is sometimes evident, and exercise sessions using higher intensities, including HIIT and SIT can produce greater benefits to SI, but not always. Indeed there remains the question of whether larger volumes of moderate intensity exercise or lower volumes of higher intensity may produce a different magnitude of adaptation, and could do so via stimulating different adaptations. Researchers are also assessing whether lower volume sessions may have the practical advantages of greater compliance, through increased enjoyment and a lesser time commitment, since lack of time is a commonly given reason for non-compliance with exercise recommendations.

While aerobic exercise interventions usually benefit SI, improvements in SI are not always associated with changes to aerobic fitness (VO$_2$ max), for reasons that may be explained by the different adaptations induced by the exercise in the cardiovascular system and peripheral musculature.

REX can improve SI through qualitative changes within the muscle as well as increases in muscle mass but the benefits are not evident in all REX studies. However there is a growing body of evidence for including both aerobic exercise and REX in exercise regimens, as this appears to more effectively improve SI than either mode of exercise alone.

The debate continues over the relative importance of exercise versus weight loss for improving SI and whether the combination of the two is more efficacious for achieving good glycaemic regulation.

The molecular bases for exercise-training induced improvements in SI are linked to increases in GLUT4 concentration and acute exercise-induced increases in Akt that deactivate TCB1D4 increasing GLUT4 translocation to the membrane, an effect that persists for several hours postexercise. Additionally, the increased capillarisation of the skeletal muscle is another factor linked to improved SI. The concentration of ceramides within muscle may provide the causal link between a high concentration of intramuscular saturated fatty acids and impaired SI.

Studies in which improvements to SI were not reported may have been a consequence of their interventions involving exercise intensities that were too low, durations that were too short or a population group whose glycaemic control was relatively good at baseline and/or were already ‘recreationally active’, and hence the capacity to change was limited.
