ABSTRACT

Background Asthma may be regarded as a contraindication to scuba diving.

Purpose A clinical algorithm to assess fitness to dive among individuals with asthma was developed and tested prospectively in clinical practice.

Study design Cohort study.

Methods All patients with possible asthma referred to Hvidovre Hospital, Denmark, for assessment of fitness to dive over a 5-year period (2013–2017) were included. Fitness to dive was assessed by case history, spirometry and mannitol challenge test. All patients with $\geq 10\%$ decline in forced expiratory volume in 1 s (FEV_1) (at any point during the challenge test) were offered step-up asthma therapy and rechallenge after at least 3 months. Patients with $< 10\%$ decline in FEV_1 after administration of a maximum dose of mannitol at the latest challenge were classified as having no medical contraindications to scuba diving.

Results The study cohort comprised 41 patients (24 men; mean age 33 years), of whom 71% and 63% of men and women, respectively, were treated with rescue bronchodilator and inhaled corticosteroid. After the first mannitol challenge test, 21 patients were classified as having no medical contraindications to scuba diving, of whom 16 were currently prescribed asthma medication. After step-up asthma therapy and rechallenge test, an additional seven patients were classified as having no medical contraindications to scuba diving. Overall, using this clinical algorithm, 28 (68%) of the referred patients were finally assessed as having no medical contraindications to scuba diving.

Conclusion Using a clinical algorithm with mannitol challenge to assess fitness to dive among patients with possible asthma and allowing a rechallenge test after step-up asthma therapy increased the proportion of individuals classified as having no medical contraindications to scuba diving. However, as this algorithm has so far not been evaluated against actual scuba diving safety, further studies are clearly needed before it can be implemented with confidence for use in clinical practice.

Clinical relevance An algorithm to assess fitness for scuba diving among individuals with possible asthma using bronchial challenge test, with the option of step-up asthma therapy and rechallenge for reassessment, has been developed for clinical use.

What is known about the subject

- The risks of diving with asthma are unknown, and it is therefore debated whether or not individuals with asthma should be excluded from diving.

What this study adds to existing knowledge

- This study developed an algorithm that increased the proportion of individuals with asthma being classified as having no medical contraindications to scuba diving.

INTRODUCTION

Since the scuba device was invented in the 1940s, it has been debated whether or not asthma should be regarded as a contraindication to diving due to multiple theoretical concerns, one of them that bronchospasm, and by that air trapping, can occur while the diver is under water. Despite several attempts, no studies have reported that diving with asthma is indeed a risk factor and therefore should be regarded as an absolute contraindication.¹ At present, there is general acceptance, not least in the diving community, that probably not all individuals suffering from asthma should be excluded from recreational diving. However, there remains no consensus on how to assess fitness for recreational scuba diving in clinical practice.² A clinical algorithm has therefore been developed (by the senior author of this study) at Hvidovre Hospital on how to assess fitness to dive in candidates with possible asthma, even though evidence is at best limited. In line with this, the objective of the present study was to test this algorithm in clinical practice.

MATERIALS AND METHODS

Characteristics of enrolled patients

All patients with asthma or possible asthma referred to Hvidovre University Hospital, Denmark, for assessment of fitness for recreational scuba diving over a 5-year period

(2013–2017) were prospectively included in the present study.

Case history was obtained from all patients. Family disposition to asthma and allergy, that is, relatives with a diagnosis of asthma or allergies, and atopic disease and symptoms, including wheezing, dyspnoea, coughing, chest tightness, recurrent lower respiratory tract infections, exercise-induced wheezing, exercise-induced cough, night-time respiratory symptoms (coughing or wheezing during night-time) and symptoms of rhinitis, were recorded together with, if relevant, previous diagnosis of asthma and currently prescribed antiasthma therapy. Patients were categorised as smokers or never smokers, and lifetime tobacco exposure was calculated as pack-years (one pack-year=20 cigarettes a day for 1 year).

Methods

Spirometry, and if spirometry revealed signs of airflow limitation also bronchodilator reversibility test, measurement of fractional exhaled nitric oxide ($F_{E}NO$) and skin prick test were performed as part of the routine work-up for patients seen at the respiratory outpatient clinic for asthma.

Spirometry

Baseline spirometry included forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1) in litres and per cent predicted³ and FEV_1 :FVC ratio. Findings from the bronchodilator reversibility test were recorded, if available.

Fractional exhaled nitric oxide

$F_{E}NO$ was measured in all patients prior to the mannitol challenge test. $F_{E}NO$ levels were measured online (rate 50 mL/s) with the nitric oxide analyser (NIOX; Aerocrine, Solna, Sweden) and according to the American Thoracic Society guidelines⁴ and expressed in parts per billion (ppb). $F_{E}NO$ was reported as the mean of two measurements.

Skin prick test

The skin prick test was done with common aeroallergens, that is, birch, grass, mugwort, horse, dogs, cats, *Dermatophagoides pteronyssinus*, *D. farinae*, *Aspergillus fumigatus*, *Alternaria iridis* and *Cladosporium herbarum*. Allergens were tested together with negative and positive controls, read after 15–20 min of application, with a positive result defined as a weal ≥ 3 mm in diameter.⁵

Mannitol challenge test

Bronchial provocation test with mannitol was performed in all included individuals as part of the clinical assessment algorithm. The mannitol challenge test was performed using a commercially available kit (Aridol/Osmohale) with prefilled capsules of mannitol at different doses (0–160 mg). The mannitol capsules were administered by inhalation in nine doses up to a cumulative dose of 635 mg (5, 10, 20, 40, 2×40, 4×40, 4×40, 4×40 mg). The FEV_1 recorded after inhalation of a 0 mg placebo capsule

constituted the value used for calculating the target value, that is, 15% decline. A standard mannitol challenge test is positive when a 15% decline from baseline in FEV_1 is observed, that is, PD_{15} . In this study, however, a positive test, that is, being classified as having no medical contraindications to scuba diving, was defined as a 10% decline from baseline in FEV_1 . The test was stopped when a cumulative dose of 635 mg was reached or if a 10% decline from baseline in FEV_1 was observed, in accordance with the guidelines of the Danish Flying and Diving Society.

Patients were told not to take rescue bronchodilators (short-acting β_2 agonist, SABA) or smoke at least 6 hours before the test, and if necessary the test was rescheduled. Patients were informed to continue using all maintenance asthma therapy as prescribed; hence, the bronchial challenge test was done on currently prescribed maintenance therapy.

Clinical algorithm for assessment of fitness to dive in patients with possible asthma

According to the national guideline, individuals with <10% decline in FEV_1 following administration of the highest dose in a bronchial challenge test with, for example, methacholine or mannitol can be regarded as having no medical contraindications to scuba diving.^{6–8} The present clinical algorithm applied mannitol challenge test. The mannitol test is an indirect bronchial provocation test which in general is more specific for identifying individuals with current airways inflammation because it causes release of mediators from inflammatory cells in the airways. The mannitol test is one of the more indirect tests (others include hypertonic saline, dry-air hyperpnoea and exercise) and is applied to this algorithm due to ease of use in everyday clinical practice. According to the algorithm, all individuals with a decline in $FEV_1 \geq 10\%$ were offered rechallenge test with mannitol after stepping up their asthma therapy, primarily increasing the dose of inhaled corticosteroid (ICS) and/or add-on long-acting β_2 agonist (LABA), after a minimum of 3 months. After the rechallenge, individuals with a decline in $FEV_1 < 10\%$ were classified as having no medical contraindications to scuba diving.

Statistical analysis

Data were analysed using SPSS V.23. The results are expressed as mean $\pm$ SD, exact number, percentages and OR with 95% CI, as appropriate. Further, when comparing the means of the divers having no medical contraindications to scuba diving versus those classified as having medical contraindications to scuba diving, independent samples t-test was used. A p value <0.05 was considered significant.

RESULTS

Baseline characteristics

A total of 41 participants were enrolled in the study (24 men), with a mean age of 33 years (range 10–69 years). Further characteristics are given in table 1.

Table 1 General characteristics of the 41 patients with asthma or possible asthma who had a mannitol challenge test as part of their assessment of fitness for recreational scuba diving

Characteristics	Total (N=41)

Predisposition to allergy*	41 (17)

The results are given in mean±SD and number of patients.

*Percentages and number of patients.

†Includes data from 38 of 41 patients.

All patients were assessed for fitness for recreational scuba diving, of whom 28 (68%) reported dyspnoea and 16 (38%) wheezing (figure 1). Levels of lung function and $F_{E}NO$ are given in table 2.

A total of 32 (78%) participants had a doctor-diagnosed asthma prior to referral for assessment of fitness to dive. Of the 41 participants, 29 were at the time of testing prescribed SABA, including 2 patients with no diagnosis of asthma, and 26 patients (63%) were prescribed maintenance therapy with ICS.

Assessment of fitness to dive using the clinical algorithm

First mannitol challenge test

All 41 enrolled participants who had a prior diagnosis of asthma or symptoms suggesting asthma had a mannitol challenge test. After the first mannitol challenge test, a total of 21 individuals had a decline of <10% in FEV_1 and were therefore classified as having no medical contraindications to scuba diving, according to the algorithm. these, 15 had a prior diagnosis of asthma. All patients with a fall of >10% in FEV_1 were offered step-up asthma therapy and a rechallenge test, but six patients did not wish to continue and were therefore assessed unfit to dive. Further details are given in table 3 and figure 2.

Mannitol challenge test after step-up asthma therapy

The remaining 20 patients were offered step-up asthma therapy and rechallenge test. Six patients did not wish to continue and were therefore assessed unfit to dive. All remaining 14 patients were prescribed a higher dose of ICS and 8 patients were also prescribed add-on LABA therapy. Details of therapy adjustments before the second mannitol challenge test are given in table 4.

At the mannitol rechallenge test, seven patients had <10% decline in FEV_1 and were therefore, according to the algorithm, classified as having no medical

Table 3 Results of initial mannitol challenge test according to current asthma therapy and outcome of the challenge test

	<10% fall in FEV_1 ; no medical contraindications to dive (n=21)	>10% fall in FEV_1 ; rechallenge offered (n=14)	>10% fall in FEV_1 ; not interested in rechallenge, unfit to dive (n=6)
SABA	14	11	4

LAMA	0	0	0

FEV_1 , forced expiratory volume in 1 s; ICS, inhaled corticosteroid; LABA, long-acting beta₂ agonist; LAMA, long-acting muscarinic antagonist; SABA, short-acting beta₂ agonist.

Figure 2 Flow chart showing the 41 candidates for recreational scuba diving tested with a mannitol challenge test and offered step-up asthma therapy and rechallenge test if there was a fall in $FEV_1 > 10\%$ in the first mannitol challenge test. Candidates with a fall $> 10\%$ in the retest were not fit for recreational scuba diving, along with candidates not interested in the retest. FEV_1 , forced expiratory volume in 1 s.

contraindications to scuba diving. Five of these individuals had a prior diagnosis of asthma. The remaining seven patients had a decline of $\geq 10\%$ in FEV_1 and were therefore classified as unfit to dive (figure 2).

Characteristics of individuals with no medical contraindications to scuba diving and individuals unfit to dive

Of the 41 patients, 28 (68%) had no medical contraindications to scuba diving, including 20 individuals with a prior diagnosis of asthma, leaving 13 individuals (32%) unfit to dive, including 1 patient with no prior diagnosis of asthma. This patient, however, had the highest level of $F_{E}NO$ (115.5 ppb) of all participants and was afterwards diagnosed with asthma and prescribed asthma therapy. The flow of patients is shown in figure 2. When comparing individuals with no medical contraindications to scuba diving with individuals unfit to dive, no significant differences were found apart from the level of $F_{E}NO$; that is, in patients with no medical contraindications to scuba

diving, the mean $F_{E}NO$ was 22.8 ± 12.4 ppb, compared with a mean of 55 ± 36.5 ppb in individuals classified as being unfit to dive ($p=0.01$).

DISCUSSION

The algorithm used in the present study to assess fitness for scuba diving in individuals with asthma, with the option of step-up asthma therapy and rechallenge, increased the likelihood of being classified as having no medical contraindications to scuba diving compared with assessments based on current national guidelines.

Comparing national guidelines

There are several published national guidelines around the world with different recommendations on how to assess diving candidates with asthma.

Strauss⁹ was the first in 1979 to suggest that contraindications to diving in subjects with asthma should include significant obstructive pulmonary disease with minimal values for FEV_1 and FVC and maximum voluntary ventilation of 75% of predicted; any asthma attack occurring within the past 2 years; the need for preventive therapy; or any episode of bronchospasm associated with exertion and/or inhalation of cold air. These contraindications are based on theoretical concerns rather than evidence, and most guidelines published since then have been based on this recommendation. Today, however, most diving experts or diving societies have more liberal approaches.

The British Thoracic Society Fitness to Dive Group (a subgroup of the British Thoracic Society Standards of Care Committee) and the Danish guidelines from the Danish Society of Respiratory Medicine share content from their respective guidelines and recommend that subjects with wheezing precipitated by exercise-induced, cold-induced or emotion-induced asthma should be excluded from diving, and that subjects with asthma should refrain from diving if they have symptoms requiring relief medication in the 48 hours preceding the dive and if they have reduced fall in peak expiratory flow (PEF) $> 10\%$ from best values or increased peak flow variability $> 20\%$ diurnal variation.^{8 10} Further, according to the Danish national guideline from the Flying and Diving Medical Society, individuals with $> 10\%$ decline in FEV_1 following administration of the highest dose in a bronchial challenge test with, for example, methacholine or mannitol are classified as unfit for scuba diving.⁸

In the USA, the National Institutes of Health in 2016 published recommendations that allow subjects with well-controlled, mild-to-moderate asthma, that is, no current chest symptoms and with normal screening spirometry, to go scuba diving. The recommendation also states that patients with exercise-induced, emotion-induced and cold-induced asthma, along with patients with asthma requiring rescue medication within 48 hours, should not dive. Furthermore, the US recommendations point to other diving societies recommending that a patient with asthma should successfully pass a bronchial provocation challenge.¹¹

Table 4 Prescribed asthma therapy at the time of the mannitol rechallenge test, according to fitness to dive (n=14)

	No medical contraindications to dive (n=7)	Unfit to dive (n=7)
SABA	5	6
ICS		
Low (200–400)	1	2
Medium (> 400 –800)	6	4
High (> 800)	0	1
LABA add-on	1	2

LABA was only administered in fixed combination with ICS. ICS, inhaled corticosteroid; LABA, long-acting beta₂ agonist; SABA, short-acting beta₂ agonist.

In Australia and New Zealand, the South Pacific Underwater Medicine Society (SPUMS) recommends that candidates who indicate a history of asthma in the last 10 years and exhibit signs of wheezing or an unexplained cough, but have normal spirometry, should have bronchial provocation test, using indirect methods including dry-air hyperpnoea, exercise and hypertonic challenges (saline or mannitol). A positive response, that is, a reduction in FEV₁ of greater than 15%, should lead to a recommendation against diving, but does not preclude retest and reassessment after asthma control has been established. Those who 'pass' bronchial provocation tests and are taking antiasthma medication should be reassessed annually or sooner if they develop any symptoms. It is further recommended that 'well-controlled' individuals with asthma, that is, asymptomatic and show normal lung function on testing with spirometry and bronchial provocation, may be able to dive at an acceptable level of risk. All current divers with controlled asthma are strongly encouraged to monitor their peak flow twice daily during diving periods, with the recommendation to refrain from diving if PEF is more than 10% below their best value.¹²

There is no worldwide consensus on assessment, and this is primarily due to the limited evidence. National guidelines are mainly based on expert opinions, case reports of diving accidents, epidemiological data, anonymous questionnaires, experimental studies with real or simulated dives, and annual reports of diving fatalities, injuries and incidents,^{13–17} and none has generated direct evidence that diving with asthma increases the risk of misadventure. Future studies should therefore address the actual risk related to recreational scuba diving in individuals with asthma and the impact on the risk of level of asthma control, and larger studies using a clinical algorithm that assesses fitness to dive are necessary.

Impact of asthma triggers on fitness to dive

Most experts seem to agree that subjects with exercise-induced, cold-induced or emotion-induced asthma should be excluded from diving.^{2 7 18–20} The SPUMS guidelines on medical risk assessment for recreational diving do not, however, take this aspect into account.¹² The present algorithm is not excluding divers with history of wheezing and/or other asthma symptoms triggered by exercise, cold or emotion, primarily due to the lack of evidence on an association between these symptoms and dive-related injuries.²¹ The concern is that the diving environment can be physically challenging and cold and trigger anxiety, and therefore cause an asthma attack. It is still worth noting that this concern is theoretical and that no evidence is indicating that candidates with exercise-induced, cold-induced or emotion-induced asthma with a negative mannitol challenge test and therefore no evidence of airway hyper-responsiveness should not be as fit to dive as other patients with asthma. Since there is no gold standard on how to assess fitness for recreational scuba diving in individuals with asthma or symptoms of asthma, this algorithm was developed for use in everyday

clinical practice, but is limited on safety since it is not known whether or not diving with asthma is an actual risk factor for injuries.

Future investigations

To know more about potential risks when diving with asthma, more studies are needed. Due to ethical concerns about performing randomised clinical trials in this setting, the use of real-world experience, registry data and surveys is the only means to gain insight into the risks and recommendations when diving with asthma or symptoms of asthma.

Study limitations

The study is limited on safety since there is no evidence on how asthma affects recreational scuba diving and therefore no gold standard for assessment of fitness to dive with asthma.

CONCLUSION

The present study tested a clinical algorithm developed at Hvidovre Hospital on how to assess fitness to dive in candidates with possible asthma. It showed an increase in the proportion of candidates being classified with no medical contraindications to scuba diving when mannitol challenge test is performed and allowing a rechallenge test after a step-up asthma therapy. However, it is important to note that this algorithm has not been evaluated against the actual safety of recreational scuba diving, and therefore further studies are clearly needed before it can be implemented safely for use in clinical practice.

Acknowledgements The authors wish to thank all participating patients and the nurses in the respiratory outpatients clinic at Hvidovre Hospital for doing the bronchial challenge tests.

Contributors CSU developed the clinical algorithm tested in the present study and is the guarantor of the study. ASU, SKP and CSU contributed to the acquisition of data. ASU and CSU analysed the data. ASU drafted the first version of the manuscript. All authors contributed to interpreting the data and revising the manuscript, and approved the final manuscript.

Funding The authors have not declared a specific grant for this research from any funding agency in the public, commercial or not-for-profit sectors.

Competing interests None declared.

Patient consent for publication Not required.

Ethics approval This study was approved by the ethics committee of the Capital Region of Denmark (H-D-2016-0051).
