THE COVID-19 PANDEMIC AFFECTS SPORTS PARTICIPATION

The Dutch Sports Participation Index showed a dramatic decrease in sports participation over 2020 and 2021 of up to 15% per month in the total population aged 5–80 years.¹ This decrease can be related to closure of sporting grounds and fitness centres, as well as the widespread advice to avoid live human interaction in striving to reduce the spread of coronavirus. Although many started a new type of sport or took part in unorganised physical activities, 22% were still less active than before the pandemic.¹ Restricted sports participation is also associated with mental health issues, more in individual than in team sport athletes.²

CHANGES IN SPORTS PARTICIPATION AND INJURY

Up until now, the COVID-19 pandemic (in) directly influenced most athletes, their teams and stakeholders. Athletes intermittently had to withdraw from training or match play, due to positive testing or ongoing changes of governmental regulations. Competitions were interrupted and matches and tournaments were postponed or cancelled. The urge of sport federations to complete competition schedules after lockdown periods conflicts with the need for adequate preparation time. Individual and team performances as well as competition outcomes may have been affected by consecutive changes in training and match play loads, which have put athletes' health at risk. Common concepts of sports participation fluctuation and associations with injury likely apply. After a period of rest between competitive seasons, a new (pre) season start is associated with increased levels of symptoms, injury incidence and burden,³ but these usually lower again during the season.

Likely due to team sport restrictions, the numbers of runners increased in The

Netherlands. This as well as novice runners being more prone to injury⁴ are thought to be the main drivers of the reported 40% increase of running-related injuries in 2020 (1.1 million) compared with 2019 (780 000).⁵ These are mostly overuse injuries, related to the lower extremity in general. Although more troublesome for athletes are the severe acute injuries (ie, from the ankle and knee). These result in longer absence from sports requiring lengthy rehabilitation periods or additional medical treatment.⁶

The 2011 NFL lockout of 20 weeks is a well-known example of sport cessation of a large group of professional athletes. Consequently, players had unstructured season preparation and a fourfold increase of acute Achilles tendon rupture rates occurred during training camp and the season start.⁷ The NFL injury registry showed that the injury numbers in the 2020–2021 season, with incomplete preseason preparation and cancelled practice matches, were higher than in the 3 years before with normal season preparation.⁸ In the German Bundesliga, match-related injury rates increased from 0.27 to 0.84 after the first strict COVID-19-related lockdown period.⁹ How sports participation restrictions relate to sports injury rates during the pandemic remains yet largely unknown.

LOCAL CLINICAL OBSERVATIONS

We have seen a steady increased influx (2-year moving average) of younger patients (≤45 years) contacting us after acute knee injury (distortion, rotation trauma, etc, during field based sports) over the past 8 years in our Dutch sports physical therapy clinic. Despite the reduction rates of general sports participation from 2019 to 2020 and 2021, these knee injury numbers still tended to rise during the 2 pandemic years. This could not be related to increased participation rates in

so-called popular 'high-risk sports' like football and field hockey, as these were contained for a long period or even closed due to COVID-19-related restrictions.

Data from our local orthopaedic surgery department show a 25% decrease of acute knee injuries and a 30% overall decrease of ACL surgery in 2021. The Dutch sports injury data registry observed a 30% reduction of football-related injuries to be presented across all hospital emergency departments in 2020.⁵

At a first glance this may seem contradictory. However, the data were not corrected for exposure time, so true risk injury estimates remain unavailable. General practitioners were holding back from referring these patients and many injured athletes have probably avoided going, to an emergency department or orthopaedic surgery setting, as media repeatedly reported hospitals to be overcrowded by patients with COVID-19. Hospital capacity available resulted in lower elective care volume; thus, we may be looking at a delay in care with a rise in the year(s) to come. Lower medical specialist visits and increased primary healthcare may indicate a shift of those seeking care, but data are not yet available to support this confidently.

BEYOND THE NUMBERS

During our clinical patient contacts, we noted that many injured athletes, with acute knee injury, attributed this, at least partially, to irregular training loads, being less prepared while restarting full training and, when allowed, (practice) match play. Decreased strength and fitness were commonly suggested factors as well as lower participation rates of sport specific training. They often noted a loss of performance in their specific context and expressed this in terms such as 'increased clumsiness', 'slower and impaired actions and reactions' and 'making more faults in decision making on the pitch'. This is likely related to longer training periods without physical contact, lacking the physical demands that keep individuals adequately prepared during contact sports.

PUTTING THE PUZZLE

The COVID-19 pandemic seems to be a relevant factor with unknown magnitude acting in the complex interplay of sports, injury and performance. Injury databases can be used for analysing this interplay, but injury numbers need to be interpreted with caution due to many changes in exposure and type of sport specific loading.

Calculating injury risk estimates and defining risk profiles regarding types of training and playing load will give more insight. This will require a huge effort as exposure times have been affected largely by temporary sporting restrictions and were different between types

of sport, competition (indoor/outdoor) or countries. Next to these quantitative analyses, qualitative explorations of how athletes themselves experienced the relation between irregular sports participation on their performance or injury will provide additional relevant information. Clinicians play an important role in asking these questions assisting in pattern recognition. This will guide collecting qualitative data that can be of help in optimising decision-making on how to deal with a comparable situation in the future.
